Keywords: Induction Motor, Direct Torque Control, Adaptive Hysteresis Band, and Constant Switching Frequency

ABSTRACT

Hysteresis band control is one of the simplest and most popular techniques used in direct torque control (DTC) of induction machine drives. However, the conventional fixed band hysteresis control has a variable switching frequency which causes serious problems in DTC. In this paper, the adaptive hysteresis band control strategy is proposed, where the hysteresis band is controlled in real time as a variation of applied voltage vectors. Thereby reducing the torque ripple whilst maintaining a constant torque switching frequency. The proposed adaptive hysteresis band control technique is verified by simulations.

1. INTRODUCTION

Recent advances in power semiconductor and microprocessor technology have made possible the application of advanced control techniques to ac motor drive systems [1]. DTC has become a popular technique for the control of induction motor drives as it provides a fast dynamic torque response and robustness to machine parameter variations without the use of current regulators. The technique can be implemented easily using two hysteresis controllers (one for flux and another for torque) and a switching table to select the switching voltage vector. However, conventional DTC suffers from such effects as torque ripple, variable switching frequency, and flux drooping at low speed. These effects result in increased sub-harmonic currents, higher load current ripple and variable switching losses in the inverter [2,3].

This paper proposes an adaptive hysteresis band control strategy, where the hysteresis band is controlled in real time as a variation of applied voltage vectors. Thereby reducing the torque ripple whilst maintaining a constant torque switching frequency.

2. GENERAL DESCRIPTION OF DTC

In general, in a symmetrical three-phase induction machine, instantaneous electromagnetic torque is a cross product of the stator and rotor flux linkage space vector or stator current space vector and stator flux linkage space vector.

\[ T_e = \frac{3}{2} p |\mathbf{\Psi}_s| |\mathbf{I}_s| \sin \gamma \]  

(1)

where \( \mathbf{\Psi}_s \) is the stator flux linkage space vector and \( \mathbf{I}_s \) is the stator space vector. In Equation (1), both space vectors are expressed in the stationary reference frame. By considering that \( \mathbf{\Psi}_s = L_s \mathbf{I}_s + L_m \mathbf{I}_r \) and \( \mathbf{\Psi}_r = L_s \mathbf{I}_s + L_m \mathbf{I}_r \), where the primed rotor quantities are expressed in the stationary reference frame, it follows that \( \mathbf{I}_r = \frac{\mathbf{\Psi}_s}{L_s} - \frac{L_m}{(L_s L_r)} \mathbf{\Psi}_r \). Thus equation (1) takes the following from

\[ T_e = \frac{3}{2} p \frac{L_m}{L_s L_r} |\mathbf{\Psi}_s| |\mathbf{\Psi}_r| \sin \gamma \]  

(2)

The electromagnetic torque given by equation (2) is a sinusoidal function of \( \gamma \), the angle between the stator and rotor flux linkage space vector.

The magnitude of the stator flux is normally kept constant and the motor torque controlled by means of the angle \( \gamma \). The rotor time constant of the standard induction machine is typically larger than 100 ms, thus the rotor flux is stable and its stable variations are slow compared with the stator flux. It is therefore possible to achieve the required torque very effectively by rotating the stator flux vector directly in a given direction as fast as possible.

Figure 1. Optimum voltage vector in the torque control and voltage vectors
The core of the system consists of a flux and torque estimator, a speed controller, a flux controller, a torque controller and an optimum switching table. The estimator estimates the actual stator flux and torque using two measured motor stator phase currents, the dc voltage and the states of the power switches. Torque and flux references are compared with the actual values and a two-level for flux and a three-level for torque hysteresis control method produces control signals.

The objective is to reduce both the stator flux and torque errors to zero using hysteresis comparators select the optimum voltage vector. Hysteresis comparators lie at the heart of DTC schemes and are responsible not only for determining the optimum voltage vector to be switched, but also for determining how long that vector or action remains selected. Hysteresis is used to prevent the power devices from switching unnecessarily at each sample update interval or switching decision. In this study, a two level hysteresis comparator, as shown Figure 2, used in DTC to compare the actual value of stator flux to the internal reference value produced by stator flux reference controller. In the similar manner, a three level hysteresis comparator, as shown in Figure 3, is used to compare the actual value of the torque to the internal reference value produced by the speed torque reference controller [4]. The outputs of these comparators are update every sampling time and they indicate whether the flux or torque has to be varied.

### 3. HYSTERESIS BAND CONTROL IN DTC

The hysteresis band control method is a simple and common form of closed-loop control. The block diagrams for the two-level and three-level hysteresis band control methods are shown figures below. Hysteresis band control is widely used because of its ability to be simply implemented. Besides the fast response the inherent peak current limiting capability and excellent dynamic performance that is offers, it does not require an accurate knowledge of the load parameters. In addition, hysteresis band control is essentially an analog technique. Despite the advantages given by the digital controllers, in terms of interfacing, maintenance, flexibility, and integration, their accuracy and response speed are often insufficient for current control in highly demanding applications, such as active filters and high precision drives. In a DTC scheme, the flux hysteresis bandwidth results in a higher switching frequency, the stator flux vector locus approaches a circle and the phase current waveform is nearly sinusoidal. These operating conditions result in low harmonic copper losses in the machine while switching losses in the inverter are high. Alternatively, a large hysteresis bandwidth for stator flux decreases the switching frequency and the stator flux vector locus becomes a hexagon. In this case the switching losses decrease in the inverter while the harmonic copper losses increase in the machine [5].

Adaptive hysteresis band has been well investigated as a two level strategy. The adaptive hysteresis band strategy can be extended to three level hysteresis band. It is demonstrated that adapting the width of the hysteresis band for the three level strategy as a function of pulse number FR and depth M. The block diagram of three level hysteresis band to be analysed is illustrated Figure 4. Output \( t_{e}(t) \) tracks the reference function \( t_{e}(t) \) to within a band whose limit is \( \Delta + \Sigma \). It is important to note the \( \Sigma \) quantity is required only to create the three voltage level in the output of the hysteresis element. In simulation
results $\Sigma$ is decrease down a very small value and for the simulation results presented in this paper it was set to be $\Delta/100$.

$$t_{on} = \frac{\Delta}{p - t_e'(t)} \quad (4)$$

The slope of output signal $t_e'(t)$ during the time $t_2 < t < t_3$ is zero because the output voltage is zero in this time period. Therefore from inspection of Figure 5, the slope of the reference function can be expressed as

$$t_e'(t) = \frac{t_e'(t_1) - t_e'(t_2)}{t_3 - t_2} = \frac{\Delta}{t_3 - t_2} \quad (5)$$

and therefore the corresponding off time may be expressed as

$$t_{off} = t_3 - t_2 = \frac{\Delta}{t_e'(t)} \quad (6)$$

By combining equation (4) and (6) the total instantaneous time period $T_i$ is described as

$$T_i = t_{on} + t_{off} = \frac{\Delta}{p - t_e'(t)} + \frac{\Delta}{t_e'(t)} \quad (7)$$

The corresponding instantaneous angular frequency, $\omega_i$, is determined by equation (8)

$$\omega_i = \frac{2\pi}{T_i} \quad (8)$$

The carrier frequency, $\omega_c$, which determines the pulse number is the average value of the instantaneous frequency, $\omega_i$, over one fundamental period and is expressed as

$$\omega_c = \frac{2}{\Delta p} \left[ 2Ae + \frac{A^2 \omega^2 \pi}{2} \right] \quad (9)$$

The analysis presented has demonstrated that the pulse number, FR, is a function of reference function amplitude, $A$, slope, $p$, of the output signal, $t_e'(t)$, and the width of the hysteresis band, $\Delta$. Therefore, it is necessary to adapt the width of the hysteresis band so that it has a constant width along a fundamental period according to Equation (10). This enable only the pulse number, FR, and depth, $M$, to be the specified parameters in the modulation process [5]. Therefore, the width of the adaptive hysteresis band can be expressed as

$$\Delta = \frac{4M \omega}{\omega_c} \left[ 1 - \frac{M \pi}{4} \right] \quad (10)$$
where $\omega_0 = FR\omega$, and the depth, $M$, is defined as

$$M = \frac{A\omega}{p} \quad (11)$$

5. SIMULATION RESULTS

A simulation study for the proposed adaptive hysteresis band control technique was carried out using the Matlab software package. The motor parameters used in the simulations are given in the appendix.

In the simulation the proposed DTC drive is operated in the speed control mode with a load of 10 nm and stator flux and rotor speed references of 0.8wb and 200 rad/s respectively. When fig. 7(b) are fig. 8(b) are compared it is observed that fig. 8(b) is circular while fig. 7(b) looks like a hexagon. It should be noted that the effect of the proposed scheme can be seen very easily at low speed from the simulation results. Constant inverter switching frequency is obtained by using adaptive hysteresis bandwidth. Furthermore, inverter switching frequency with adaptive hysteresis band is obtained and this is illustrated in figure 6. In addition, switching frequency is small at low speeds. In order to increase the switching frequency the torque adaptive hysteresis band width is decreased. Thus stator flux locus becomes circular. In conclusion, the obtained simulation results fig. 7(a) and 8(a), fig. 7(b) and 8(b), fig. 7(c) and 8(c), fig. 7(d) and 8(d) are shown for comparison.

6. CONCLUSIONS

In this paper a adaptive hysteresis band control strategy, where the band is controlled as variation of applied voltage vectors in order to keep the switching frequency constant at any operating conditions is proposed. The proposed control technique is verified by simulations. With proposed technique, the switching frequency of the inverter is nearly held constant.
